The Importance of Structure

The importance of structure: mesocosm evidence for shelter design in freshwater crayfish restoration

Olivier V. Raven, Robin Holmes, Ian A. K. Kusabs, Francis J. Burdon & Deniz Özkundakci

1 Abstract

2 Freshwater crayfish are keystone species that rank among the most threatened invertebrate
3 groups globally. While habitat loss and predation by non-native predators feature prominently
4 as drivers of crayfish population declines, the optimal design of habitat enhancement structures
5 for their restoration remains largely unknown. To better understand freshwater crayfish habitat
6 preferences, our study focussed on the endemic kōura (*Paranephrops planifrons*) found in
7 Aotearoa New Zealand. We used four mesocosm experiments to examine how shelter structure,
8 material composition, individual body size, and group dynamics influence refuge selection in
9 kōura. Individual kōura strongly preferred a wooden log with enclosed drilled holes, but when
10 housed in mixed-size groups, their preference shifted to flat and piled stone configurations
11 that provided more complex refugia for individuals of different sizes. Flat stone structures
12 were preferred over split wood pieces of similar dimensions, and this was strongest for large
13 individuals. When structural dimensions were held constant, no significant preference was
14 detected between concrete and wooden structures, indicating that material composition alone
15 does not drive refuge selection. The findings of these mesocosm experiments suggest that
16 stone pile configurations warrant field evaluations as habitat enhancement structures for kōura
17 restoration. The stone piles create structural complexity that can provide habitat for different
18 size classes and thus may add critical refuge from non-native predators for kōura populations.

19 Introduction

20 Freshwater biodiversity is declining faster than in any other ecosystem globally, driven by
21 habitat loss, pollution, and invasive species (Dudgeon *et al.*, 2006). Crayfish are among the
22 most threatened freshwater invertebrates, with 32 % of species assessed as threatened with
23 extinction due to these same pressures (Richman *et al.*, 2015). As keystone species and
24 ecosystem engineers, crayfish play crucial roles in freshwater food webs through shredding of
25 leaf litter, bioturbation of sediments, and nutrient cycling, and their loss can have profound
26 cascading effects on freshwater ecosystems (Momot, 1995; Collier *et al.*, 1997; Parkyn *et al.*,
27 2001). The increasing degradation of freshwater habitats therefore not only threatens crayfish
28 populations but also risks disrupting the ecosystem processes crayfish sustain.

29 Habitat complexity is a key driver of crayfish population persistence, as structurally diverse
30 habitats provide physical refugia from predators, foraging opportunities, and shelter during
31 moulting when individuals are particularly vulnerable (Hammond *et al.*, 2006). Shelter

1 availability directly increases crayfish survival and growth under predation pressure ([Adams,](#)
2 [2007](#)), making refuge quality a critical consideration for both natural habitat persistence and
3 restoration design. Crayfish use a wide variety of natural and artificial structures as shelter,
4 including rocks, woody debris, and even anthropogenic objects such as bottles and discarded
5 appliances ([Parkyn *et al.*, 2009](#); [Adams, 2014](#)), demonstrating considerable flexibility in habitat
6 use. While this diversity of potential refugia is well documented, preferences among different
7 structure types remain poorly understood, even though knowledge of habitat preferences is
8 fundamental to designing effective enhancement structures for restoration. In the context of
9 freshwater restoration, increasing structural complexity through providing shelters has improved
10 crayfish abundance and restocking success in degraded streams and lakes ([Huolila *et al.*, 1997](#);
11 [Johnsen and Taugbøl, 2008](#)), and the availability of coarser substrate has also been shown to
12 improve juvenile survival rates ([Mazlum *et al.*, 2017](#)). These findings indicate that enhancing
13 habitat complexity can be a useful management tool for threatened crayfish populations, yet
14 systematic comparisons of shelter configurations for freshwater crayfish restoration remain
15 largely absent from the literature.

16 Shelter selection in crayfish is strongly influenced by body size, as individuals actively select
17 refugia proportional to their dimensions. Crayfish individuals tend to select stones more than
18 3 times longer and 1.25 times wider than their carapace length, with larger males consistently
19 selecting larger stones ([Streissl and Hödl, 2002](#)). Social dynamics further complicate shelter use
20 when refuge availability is limited, as competitive interactions among conspecifics determine
21 which individuals gain access to preferred shelters. Dominance hierarchies based on body size
22 and reproductive status show that males and maternal females often are able to take over shelters
23 from non-maternal females, while adults consistently outcompete juveniles for shelter access
24 ([Figler *et al.*, 2005](#)). Body size and shelter dimensions have direct competitive consequences as
25 crayfish in undersized shelters initiated and won more fights than those in appropriately sized
26 shelters, suggesting that shelter fit influences an individual's assessment of its own fighting
27 ability ([Percival and Moore, 2010](#)). Body size ratios between contestants are a strong predictor
28 of shelter takeover success, although prior ownership can offset size disadvantages ([Ranta and](#)
29 [Lindström, 1993](#)), particularly when both individuals hold high-quality shelters ([Takahashi *et*](#)
30 [al., 2019](#)). At the population level, habitat complexity buffers these competitive effects, with
31 juveniles in structurally complex habitats showing higher survival, faster growth, and greater
32 moulting rates as more shelter availability reduces agonistic interactions ([Olsson and Nyström,](#)
33 [2009](#)). Together, shelter use in crayfish reflects an interaction between individual body size and
34 social competitive dynamics, suggesting that effective habitat enhancement structures must
35 provide a range of shelter sizes to support different life stages and size classes simultaneously.

1 The material and structural properties of shelters can influence their value as refugia. In a
2 study comparing shelter configurations on reef fish assemblages, the availability and size of
3 enclosed spaces mattered more than total structure volume (Hylkema *et al.*, 2020). Additionally,
4 enclosed structures such as PVC pipes provide greater protection against predatory fish than
5 stone or vegetation structures, likely due to their consistent hole dimensions (Zhao *et al.*, 2024).
6 However, the use of synthetic materials like PVC pipes in restoration ecology brings ecological
7 concerns, particularly in contexts where introducing non-native materials may conflict with
8 conservation values or indigenous cultural frameworks (Wehi and Lord, 2017; Cooke *et al.*,
9 2023). Natural materials such as stones and wood offer ecologically compatible alternatives,
10 yet the importance of structural configuration versus material composition for crayfish shelter
11 preference is poorly understood.

12 In Aotearoa-New Zealand (hereafter Aotearoa), the endemic freshwater crayfish kōura
13 (*Paranephrops planifrons*) faces conservation pressure from habitat loss, water quality
14 degradation, and predation by invasive species (Lee *et al.*, 2025; Kusabs *et al.*, 2026). Kōura are
15 a taonga (culturally treasured) species for Māori, the indigenous people of Aotearoa, and hold
16 significant ecological and cultural value in freshwater ecosystems (Kusabs *et al.*, 2015a; Kusabs
17 and Quinn, 2009). In their natural habitat, kōura are positively associated with overhanging
18 banks, coarse substrates, and woody debris (Raven *et al.*, 2026a; Usio and Townsend, 2000;
19 Jowett *et al.*, 2008; Parkyn *et al.*, 2009). Kōura have been shown to significantly increase
20 refuge use in the presence of predators (Raven *et al.*, 2026b; Shave *et al.*, 1994). Habitat
21 restoration by increasing shelter availability represents a promising management tool for kōura
22 recovery, and the use of natural materials aligns with ecological and cultural values.

23 In this study, four mesocosm experiments were conducted to identify kōura habitat preferences.
24 We assessed how different structures varying in material and configuration influence refuge
25 selection, accounting for individual behaviour, body size, and group interactions. We predicted
26 that 1) Structurally complex structures providing enclosed crevices would be preferred over
27 isolated or open structures, as enclosed spaces reduce predation risk; 2) structure preference
28 would be size-dependent, with larger kōura selecting structures with larger refuge spaces (Streissl
29 and Hödl, 2002; Percival and Moore, 2010); 3) stone-based structures would be preferred over
30 wood due to greater structural stability, and 4) material type alone would not influence refuge
31 preference between concrete and wooden bricks. The results provide practical guidance for
32 designing cost-effective, ecologically appropriate habitat enhancement structures to enhance
33 kōura abundance and support population recovery.

Materials and Methods

Animal collection and tank setup

In mid-August 2025, 72 kōura were sourced from Lakes Ōkāreka and Tikitapu, located within the Rotorua Te Arawa Lakes area in the North Island of Aotearoa. Collected animals were transported to the Aquatic Research Centre at the University of Waikato in Hamilton. Individuals were assigned to one of three size classes based on orbital carapace length (OCL): small (< 22 mm), medium (22–30 mm), and large (> 30 mm). Each animal was marked with a unique identification number written on the carapace using an orange oil-based paint marker (Sharpie, medium point) (Ramalho *et al.*, 2010).

Kōura were acclimatised for 12 days in outdoor concrete holding tanks (Ø 1.4 m), each filled to 0.4 m with dechlorinated tap water conditioned for three months, paving sand as substrate, shelters, and were covered with a single layer of shade cloth. Each holding tank housed 10–12 individuals. Kōura were fed every second day with commercial carnivore pellets (Hikari Tropical, Kyorin Food Industries Ltd., Japan; animal protein 47 %). Water temperature and dissolved oxygen remained stable throughout the experimental period (temperature: 12 ± 1.2 °C; dissolved oxygen: 99.9 ± 1.7 %).

Experiments were conducted in six larger outdoor concrete tanks (1425 L; Ø 1.85 m) with the same substrate and water conditions, covered with a double layer of shade cloth to prevent escape and minimise solar heating. Fresh dechlorinated tap water and an air stone were added between rounds. To limit thermal stress, experiments were conducted during the Australasian spring (September to October). Because kōura are a taonga (treasured) species, permission to conduct the experiments was obtained from Te Arawa Lakes Trust and Te Komiti Whakahaere. All experimental procedures were conducted under University of Waikato animal ethics committee approval (protocol number: 1207; see Ethical Approval section).

Experiment 1: Individual preference

This experiment assessed individual kōura structure preference by offering single animals a choice among four structures (Figure 1). The structure-types were: SingleStone (ten quarried stones (150–250 mm) placed individually across the quadrant with sufficient spacing between stones that no crevices formed between them), FlatStone (ten quarried stones arranged tightly without stacking), StonePile (ten quarried stones stacked to form a pile), and WoodLog (a

1 tānekaha (*Phyllocladus trichomanoides*) log (500 mm long, 150 mm diameter) containing six
2 drilled holes (70 mm deep, 32 mm diameter)). If a kōura was not using a structure, TankWall
3 was noted as its location which represents the wall of the tank or when the kōura was in the
4 open. TankWall functioned as an indicator of structure rejection rather than a preference.
5 Six experimental tanks were used, each housing a single medium-sized kōura. Across five
6 experimental replicates, a total of 30 kōura were tested, consisting of 15 females with mean
7 OCL and weight $\pm$ SD: 26.9 ± 2 mm, range: 23.2–29.8 mm, 12.5 ± 3.3 g and 15 males: $26.1 \pm$
8 2.2 mm, range: 22.6–30 mm, 11.9 ± 3.1 g. Each replicate lasted 22 hours, beginning at noon
9 (12:00) and ending at 10:00 the following morning.

10 Each experimental tank was divided into four quadrants, with one structure type placed at
11 random (randomizer.org) in each quadrant. For each trial, a single kōura was placed inside
12 a vertically oriented plastic tube (50 mm long, open at one end and sealed at the other)
13 positioned at the centre of the tank, with the sealed end resting on the substrate. This ensured
14 a standardised starting position from which the kōura could exit in any direction (MacNeil *et*
15 *al.*, 2025). The time taken for the kōura to locate its initial refuge location was recorded. On
16 the following day, the final location of the kōura was noted after which it was removed from
17 the tank. Tanks were reset and structure placements re-randomised prior to the next trial.
18 Each individual kōura was used once in a single trial and not reused across temporal replicate
19 blocks. To confirm nocturnal activity, three digital cameras (GoPro Hero 3) were placed in one
20 tank and recorded for five hours at the end of each of the five days.

21 **Experiment 2: Group dynamics**

22 Building on Experiment 1, this experiment examined how group dynamics and body size
23 influenced structure preference when kōura were housed together. The same six experimental
24 tanks were used and configured with the identical structure types and randomisation procedure
25 as in Experiment 1 (Figure 1). In contrast to the single-animal trials, each tank housed a
26 group of six male kōura, as male-only groups simplified competitive dynamics and size class
27 assignment given limited female availability. Groups were comprised of two small, two medium,
28 and two large individuals. Size classes were defined by OCL: small (mean OCL and weight
29 $\pm$ SD: 19.2 ± 2 mm, range: 15.8–21.6 mm, 3.9 ± 2.1 g), medium (26.4 ± 1.6 mm, 23.5–29.5
30 mm, 11.6 ± 2.4 g), and large (36.3 ± 4.2 mm, 30.7–43.3 mm, 31.8 ± 11.2 g). Each group was
31 introduced to the centre of the tank within an open-top plastic container (150 $\times$ 150 $\times$ 85
32 mm). The container was removed, and the initial location of each individual was recorded. On

1 the following day, the final location of each kōura was documented, before all individuals were
2 removed from the tank. This procedure was repeated across five experimental replicate blocks,
3 resulting in 30 group-trials in total (six groups $\times$ five blocks). Structure placements and tank
4 assignments were re-randomised between blocks, such that each group was housed in a different
5 tank in each successive round. The same six groups were reused across all five blocks, with
6 individuals staying with their assigned group between replicates. No mortality occurred during
7 the experiment.

8 **Experiment 3: Wood vs Stone**

9 Using the same male kōura groups from Experiment 2, this experiment narrowed the choice to
10 two structure types, stone and wood, to directly compare preference between these materials.
11 The structure types were: (1) a flat stone structure (FlatStone) constructed from twelve stones
12 placed tightly together, and (2) a wood structure consisting of twelve wood splits (WoodSplit)
13 made from the tānekaha logs (Figure 1). Each group was released at the centre of the tank,
14 and the initial structure selected by each kōura was recorded. The following day, the final
15 location of each kōura was documented. This procedure was repeated across three experimental
16 replicate blocks, resulting in 18 group-trials in total (six groups $\times$ three blocks). Structure
17 placements and tank assignments were re-randomised between blocks, such that each group
18 was housed in a different tank in each successive round. One small individual died in the first
19 block and was replaced with a size-matched individual to maintain group composition. One
20 individual could not be located at the end of the final block and was assumed to have escaped
21 the tank.

22 **Experiment 4: Material comparison**

23 This experiment tested whether kōura showed a preference between perforated concrete bricks
24 and perforated wooden blocks to further identify the effect of material on structure preference.
25 Two perforated building bricks (ConcreteBrick) of $80 \times 80 \times 225$ mm with five holes ($\varnothing$ 30 mm)
26 were tested against two wooden blocks (WoodBlock) with drilled holes made from Western red
27 cedar (*Thuja plicata*), constructed to match the building bricks in external dimensions and
28 hole size. To prevent floating, a solid clay brick of identical dimensions was placed on top of
29 each WoodBlock. ConcreteBrick did not require additional weight (Figure 1). New groups of
30 ten kōura and four experiment tanks were used for this experiment, comprising a total of 40

1 individuals consisting of 18 females with mean OCL and weight $\pm$ SD: 26.2 ± 3.1 mm, range:
2 20.2–30.8 mm, 12.2 ± 4.2 g and 22 males: 26 ± 2.1 mm, range: 20.9–29.5 mm, 11.6 ± 3.2 g.
3 Due to reduced animal availability, individuals were drawn from a slightly broader size range
4 than medium-size individuals, resulting in unbalanced size class representation (small: $n = 4$,
5 medium: $n = 35$, large: $n = 1$). In each of the four experimental tank quadrants one structure
6 was placed, with similar structure types positioned opposite to one another. Each group of
7 kōura was released at the centre of the tank and the following day, the final location of each
8 kōura was documented. This experiment was repeated across four temporal blocks using the
9 same four groups of ten kōura, resulting in 16 group-trials in total (four groups $\times$ four blocks).
10 Structure placements and tank assignments were re-randomised between blocks, such that each
11 group was housed in a different tank in each successive round.

12 Data analysis

13 Experiment 1: To test the difference between the four structure types selected by the single
14 kōura, a multinomial goodness-of-fit test was performed using the XNomial package ([Engels,](#)
15 [2014](#)). TankWall was excluded from preference tests as it represents the absence of structure
16 choice rather than a structure type preference. Additionally, pairwise likelihood-ratio G-tests
17 with Bonferroni correction were used to identify which structure types differed significantly
18 from each other. Bayesian categorical mixed-effects models were used to test whether body
19 size or sex affected structure preference across all experiments, fitted using the brms package
20 ([Bürkner, 2017, 2018](#)). For Experiments 1 and 2, where kōura chose among four structure
21 types, a categorical family was used. For Experiments 3 and 4, where only two structure types
22 were directly compared, a Bernoulli family was used. Model convergence was assessed using
23 the Gelman-Rubin diagnostic (all $\hat{R} = 1.00$) and divergent transition counts (all experiments:
24 0 divergences), confirming reliable posterior sampling ([Gelman and Rubin, 1992](#)). To test
25 whether structure type use differed between sexes, the Bayesian categorical mixed-effects model
26 was fitted with structure type as the outcome, sex as a fixed effect and tank and experimental
27 round as random intercepts. A permutation-based symmetry test was applied to assess whether
28 structure type transitions between initial location and next-day location were directional rather
29 than random.

30 Experiment 2: To test whether overall structure preference existed at the group level, one-
31 sample Wilcoxon signed-rank tests were applied to group-round proportions for each structure
32 type, testing against a null expectation of 0.25 (equal distribution among four structure

Figure 1: Overhead photographs of experimental tank configurations for each of the four mesocosm experiments. Experiment 1 (Individual preference) and Experiment 2 (Group dynamics): four shelter types, WoodLog (tānekaha log with drilled holes), FlatStone (stones arranged flat), StonePile (stones stacked), and SingleStone (individual stones placed separately). Experiment 3 (Wood vs Stone): WoodSplit shelter (tānekaha wood splits) and FlatStone shelter placed in opposing halves of the tank. Experiment 4 (Material comparison): ConcreteBrick (perforated concrete bricks) and WoodBlock (perforated wooden blocks of identical dimensions) placed in opposing quadrants of the tank.

types). P-values were Bonferroni adjusted for multiple comparisons. Normal approximation was used due to ties arising from discrete group counts. To test whether size classes affected structure preference while accounting for repeated measurement of individuals and groups, the Bayesian categorical mixed-effects model was fitted with structure type as the outcome, size class as a fixed effect, and group identity, individual identity nested within group, and tank and experimental round as random intercepts. The Stuart-Maxwell test was used to test for statistical differences between initial and next-day location.

Experiment 3: To test the difference between FlatStone and WoodSplit the Wilcoxon signed-rank test was applied to group-round proportions for each structure type, testing against a null expectation of 0.5. P-values were Bonferroni adjusted. To test whether size classes affected structure preference while accounting for repeated measurement of individuals and groups, the Bayesian Bernoulli mixed-effects model was fitted with size class as a fixed effect, following the same random effects structure as described for Experiment 2. The Stuart-Maxwell test was used to test for statistical differences between initial and next-day location.

Experiment 4: To test whether kōura showed a preference between ConcreteBrick and WoodBlock, the Wilcoxon signed-rank test was applied to group-round proportions for each structure type, testing against a null expectation of 0.5 and p-values were Bonferroni adjusted. A paired Wilcoxon signed-rank test was used to directly compare group-round proportions between ConcreteBrick and WoodBlock. As size class was unbalanced, the effect of sex on structure preference was tested using the Bayesian Bernoulli mixed-effects model with sex as a fixed effect, following the same random effects structure as described for Experiment 2. Finally, as only next-day locations were recorded in this experiment, no directional shift analysis was performed.

Results

Experiment 1: Individual preference

Individual kōura showed a strong preference for WoodLog, selecting it significantly more often than SingleStone, FlatStone, and StonePile (pairwise G-test, Bonferroni adjusted: $p < 0.001$, 0.011, 0.004, respectively; overall multinomial test: $p < 0.001$; Figure 2). No significant differences were found among the stone structure types. Overall, WoodLog was selected by 67 % of kōura at refuge (males: 80 %; females: 53 %), and no kōura were found at TankWall. Sex had no credible effect on structure preference ($\beta = 3.32$, 95% CI: -1.09 to 9.3; posterior

1 probability = 0.92) with credible intervals spanning zero for all structure types. The symmetry
 2 test indicated that structure type use shifted between initial and next-day location ($p < 0.001$),
 3 suggesting kōura actively relocated to preferred structure types overnight rather than remaining
 4 at their initial location. The video footage showed kōura emerging, walking and climbing on
 5 the structures after sunset.

Figure 2: Proportion of individual kōura (Experiment 1) found at each structure type the next day, shown separately for female (white bars) and male (black bars) kōura. Bars show observed proportions with sample sizes (n) shown on bars. Letters above bars indicate results of pairwise G-tests with Bonferroni correction within each sex group, structure types sharing the same letter within a panel do not differ significantly from each other, while structure types with different letters differ significantly in use. No significant difference in overall structure preference was detected between sexes (see results).

6 Experiment 2: Group dynamics

7 When housed in mixed-size groups, kōura showed a significant overall preference for stone-based
 8 structures (Figure 3). FlatStone was used significantly more ($p = 0.004$), while SingleStone (p
 9 < 0.001) and WoodLog ($p = 0.039$) were significantly avoided. StonePile did not differ from
 10 random expectation ($p = 1.000$) and did not differ significantly from FlatStone ($p = 0.117$).
 11 No kōura were found at TankWall, indicating active structure selection across the group. Size

1 classes had limited but credible effect on structure preference. Medium-sized kōura showed a
 2 weaker preference for FlatStone over SingleStone compared to small kōura ($\beta = -1.77$, 95% CI:
 3 -3.7 to -0.14 ; posterior probability = 0.99), while no other size class effect was credible. Overall,
 4 FlatStone remained the most selected structure type across all size classes, but its strength
 5 of preference declined from small (posterior probability of top choice = 82 %) to medium (53
 6 %), and with large kōura showing similar preference between FlatStone and StonePile (42
 7 % vs 38 %). Structure type use shifted directionally between initial and next-day location
 8 (Stuart-Maxwell test: $p = 0.001$), indicating that kōura actively relocated to preferred structure
 9 types overnight.

Figure 3: Structure type preference of group kōura (Experiment 2). (A) Proportion of kōura found at each structure type at L1 across all groups and rounds. The dashed line indicates the null expectation of equal distribution (0.25). Significance symbols indicate deviation from null expectation (Wilcoxon signed-rank test, Bonferroni adjusted): ↑ used more than expected, ↓ used less than expected. Sample sizes shown in white. (B) Posterior predicted probability of structure type use by size class from Bayesian categorical mixed model, with 95 % credible intervals.

10 Experiment 3: Wood vs Stone

11 Kōura consistently selected FlatStone over WoodSplit, with the preference growing with body
 12 size (Figure 4). At the group level, FlatStone was used significantly more than expected ($p =$
 13 0.001), while WoodSplit was significantly avoided ($p = 0.004$). Only one kōura was found at
 14 TankWall. The Bayesian model indicated that preference for FlatStone strengthened with body
 15 size, with the posterior probability of FlatStone being the top-ranked structure increasing from

1 small (66 %) to medium (79 %), to large kōura (99 %). Large kōura showed a particularly
2 strong and credible preference for FlatStone over WoodSplit ($\beta = -2.55$, 95% CI: -4.7 to -0.9;
3 posterior probability = > 0.99), while medium kōura did not differ from small kōura. Structure
4 type use shifted directionally between initial and next-day location (Stuart-Maxwell test: $p =$
5 0.003), with kōura relocating toward FlatStone overnight.

Figure 4: Structure type preference in stone versus wood comparison (Experiment 3). (A) Proportion of kōura found at each structure type at next-day location across all groups and rounds. The dashed line indicates the null expectation of equal distribution (0.5). Significance symbols as in Figure 3. (B) Posterior predicted probability of structure type use by size class from Bayesian categorical mixed model, with 95 % credible intervals. ↑ used more than expected, ↓ used less than expected. TankWall excluded from model predictions.

6 Experiment 4: Material comparison

7 Kōura used both structure types, showing no significant preference between ConcreteBrick and
8 WoodBlock ($p = 0.137$; Figure 5), with mean group proportions of 47 % and 53 % respectively.
9 Neither structure type differed significantly from equal distribution ($p = 0.273$). 9 % of kōura
10 were found at TankWall, which is higher than in any previous experiment, likely reflecting
11 the smaller total structure size in this experiment rather than active structure avoidance. Sex
12 had no credible effect on preference between structure types ($\beta = -0.18$, 95% CI: -1.24 to 0.84;
13 posterior probability = 0.65), indicating that both structures were equally suitable refuge for
14 male and female kōura.

Figure 5: Material preference (Experiment 4). (A) Proportion of kōura found at each structure type at next-day location across all groups and rounds. The dashed line indicates the null expectation of equal distribution (0.5). (B) Posterior predicted probability of structure type use by sex from Bayesian categorical mixed model, with 95 % credible intervals. TankWall excluded from model predictions.

1 Discussion

2 Structure matters more than material

The consistent finding across all experiments that structural stability and cavities complexity determined preference, regardless of whether the comparison involved material type, configuration or group size, suggests that kōura, like many refuge-dependent crustaceans (Zimmer-Faust and Spanier, 1987; Beck, 1995; Streissl and Hödl, 2002; Pirtle *et al.*, 2012), are primarily selecting for physical shelter quality rather than material familiarity. When hole dimensions were held constant between concrete and wooden perforated structures, no preference for either material was detected, demonstrating that material composition alone may not drive refuge selection when structure is equivalent. Neither structure type was conditioned prior to experiments, meaning biofilm colonisation that occurs in natural lake environments was absent. As stone and wood develop different biofilm communities (Tank and Winterbourn, 1996), material preference in field settings could change. The wooden structures required a clay brick placed on top to prevent floating, creating a difference with the concrete structures, though the absence of any preference suggests this did not meaningfully influence the result. This material-independence broke down when material affected structural properties: when flat-laid stones were compared

1 against similarly sized split wood pieces, kōura showed a clear preference for stone. The wood
2 splits, being less dense than stone, sank but created less structurally stable refuge places in the
3 sandy substrate than the stones, as larger kōura were able to move them [O.V. Raven, pers.
4 obs.].

5 In group settings, structures providing the most crevice complexity were strongly preferred,
6 with flat-laid stones accommodating the most kōura, followed by stone piles. Individual kōura
7 showed a different preference, consistently choosing the perforated wooden log over all stone
8 options, which is consistent with our first prediction that structurally complex and enclosed
9 refugia would be preferred as enclosed spaces reduce predation risk (Jurcak *et al.*, 2016). The
10 individual drilled holes in the wooden log offered protection similar to what has been found for
11 perforated brick and PVC tube shelters in response to the threat of catfish predation (Adams,
12 2007; Zhao *et al.*, 2024). The directional shift in structure type use, between initial locations
13 shortly after release and their location following a night within the tank, confirmed across
14 all experiments that kōura actively relocated overnight, supporting the interpretation that
15 next-day locations reflect genuine refuge preference rather than chance displacement.

16 The shift from the perforated wooden log in individual trials to stone structures in group trials
17 was unexpected. The wooden log contained six individual drilled holes, so capacity was not
18 limiting for the group of six kōura. The preference shift may partly reflect size mismatch
19 between fixed hole dimensions, and the range of body sizes present in each group, with only
20 medium-sized individual finding the holes well-suited, while small and large individuals were
21 better served by the range of crevices created by the stone structures (Streissl and Hödl, 2002).
22 However, a more fundamental explanation may relate to social behaviour. The wooden log
23 was the most selected structure in round 1 of Experiment 2 (17 out of 36 times), similar to
24 Experiment 1, but this preference did not persist in subsequent rounds. This shift suggests that
25 once kōura had experienced sharing the tank, they adjusted their shelter use toward structures
26 allowing closer conspecific proximity. Gregarious shelter behaviour has been documented in
27 juvenile burrowing crayfish (Hazlett *et al.*, 2007; Reynolds *et al.*, 2013; Clay *et al.*, 2017) and is
28 well established in lobsters including the New Zealand rock lobster (*Jasus edwardsii* Hutton,
29 1875) (Butler *et al.*, 1999), where conspecific chemical cues attract individuals to share refugia
30 and find refugia significantly faster, reducing predation exposure (Zimmer-Faust and Spanier,
31 1987; Childress and Herrnkind, 2001). Whether kōura exhibit similar gregarious tendencies
32 remains understudied, but the preference shift observed in this study, might suggest that social
33 context alters shelter preferences.

1 **Body size and competitive dynamics**

2 Size class consistently influenced refuge preference across experiments, but the pattern differed by
3 context. In Experiment 3, larger kōura showed a stronger preference for flat stones over wooden
4 splits than smaller individuals, consistent with size dependent shelter selection documented in
5 crayfish (Streissl and Hödl, 2002; Percival and Moore, 2010). This may reflect larger kōura
6 being more capable of asserting dominance over preferred stable refugia through competitive
7 displacement, which is consistent with the size-based dominance hierarchy documented in kōura
8 populations (Ranta and Lindström, 1993; Figler *et al.*, 2005; Stewart and Tabak, 2011). In
9 Experiment 2, where four structure types were available, small kōura showed the strongest
10 preference for flat stones while large kōura distributed more evenly between flat stones and stone
11 piles, suggesting that the large continuous surface area of the flat stones provides refuge spaces
12 proportional to smaller body dimensions (Streissl and Hödl, 2002), while larger individuals find
13 adequate crevice space in either stone configuration. The absence of sex effects in Experiments 1
14 and 4 suggests that refuge preference in kōura is driven primarily by body size and competitive
15 dominance rather than sex (Figler *et al.*, 1999). When refuge availability is limited, competitive
16 hierarchies displace smaller and recently moulted individuals from preferred refugia, leaving
17 them exposed (Ranta and Lindström, 1993; Figler *et al.*, 2005). Providing sufficient refuge
18 spaces with a range of crevice size can reduce agonistic interactions and benefit the whole
19 population (Olsson and Nyström, 2009), supporting complex structure configurations over
20 structures with fixed hole dimensions.

21 **Restoration implications**

22 With the threat from invasive predatory fish, such as catfish preying on kōura (Kusabs *et*
23 *al.*, 2026), enhancing habitat complexity may reduce top-down control on kōura populations.
24 Additional habitat as used here can provide shelter spaces and offers a promising management
25 tool, as refuge availability directly influences predation survival (Adams, 2007; Zhao *et al.*,
26 2024). The present study demonstrates that structural configuration and stability drive
27 refuge preference more strongly than material composition, with stone-based configurations
28 preferred by groups and no preference detected between materials when dimensions were equal,
29 suggesting that stone-based habitat enhancement structures warrant field evaluation in lake
30 environments.

31 The broader restoration literature supports both the structural principle and the choice of

1 natural materials. Structurally stable crevices are important for freshwater species like crayfish
2 (Huolila *et al.*, 1997; Streissl and Hödl, 2002), but also for marine environments, as reef fish,
3 marine shrimp, and lobsters have all been shown to benefit from habitat enhancement structures
4 such as artificial reefs (Spanier, 1994; Magnelia *et al.*, 2008; Hylkema *et al.*, 2020; Dickson *et*
5 *al.*, 2023). Structures made from stone and wood have been shown to outperform synthetic
6 alternatives and bare substrates (Huolila *et al.*, 1997; Magnelia *et al.*, 2008; Cooke *et al.*, 2023;
7 Dickson *et al.*, 2023), and do not contribute to plastic pollution in the environment (Cooke
8 *et al.*, 2023). Locally sourced natural materials also align with *kaitiakitanga*, which is the
9 Māori principle of environmental guardianship and preserves the natural character of culturally
10 significant lake environments (Clapcott *et al.*, 2018). Furthermore, existing habitat surveys
11 suggest that kōura are associated with coarser substrates (Kusabs *et al.*, 2015b; Olsson *et al.*,
12 2006; Jowett *et al.*, 2008), and cobbles have previously been used in stream and lake restoration
13 (Huolila *et al.*, 1997; Johnsen and Taugbøl, 2008). For in-lake deployment stone pile structures
14 are likely to be the most practical configuration, due to their elevated structure, stone piles are
15 less likely to be buried into soft substrates than flat individual rocks (Garron *et al.*, 2024). Field
16 validation in lake environments remains an essential next step, as in-lake conditions including
17 water movement, natural substrate, and predator pressure may modify kōura preferences in
18 ways not captured under controlled conditions.

19 Conclusion

20 Across four mesocosm experiments, structural configuration and crevice complexity consistently
21 predicted kōura shelter preference more strongly than material composition. The shift from
22 individual preference for enclosed wooden log shelters to group preference for stone configurations
23 shows that social context plays a key role in determining shelter value for kōura. Size-dependent
24 preferences further suggest that structures accommodating multiple body sizes simultaneously
25 benefit whole populations rather than only dominant individuals. Stone-based structures using
26 locally sourced materials are promising candidates for field evaluation, aligning with ecological
27 and cultural values associated with restoring this taonga species. Field validation remains
28 the essential next step for translating these findings into effective kōura habitat restoration
29 practice.

1 **Acknowledgements**

2 We thank Te Arawa Lakes Trust and Te Komiti Whakahaere for the opportunity to collect
3 and study the treasured kōura. We are grateful to Soweeta Fort-D'ath and William Anaru (Te
4 Arawa Lakes Trust), and Tihini Grant (Ngāti Pikiao).

5 **Funding statement**

6 This research was supported by the Fish Futures programme funded through a Ministry of
7 Business, Innovation and Employment grant (CAWX2101) with additional funding provided by
8 the Bay of Plenty Regional Council under the Toihuarewa Waimāori - Bay of Plenty Regional
9 Council Chair in Lake and Freshwater Science programme.

10 **Authors' contributions**

11 Study conception and design were undertaken by O.V.R., R.H. and F.J.B. Experiments were
12 conducted by O.V.R. Data analysis was performed by O.V.R. I.A.K.K. obtained iwi consent,
13 provided local ecological knowledge and kōura specimens. Manuscript drafting was led by
14 O.V.R. All authors contributed to manuscript revision, approved the results, and the final
15 manuscript.

16 **Ethical approval**

17 This study received ethical approval by University of Waikato animal ethics committee, protocol
18 number: 1207. Additional permission to conduct experiments with kōura was granted by Te
19 Arawa Lakes Trust and Te Komiti Whakahaere.

20 **Declarations**

21 The corresponding author has declared that none of the authors has any competing interests.

1 Data availability statement

2 The code and derived data supporting the findings of this study are openly available on GitHub
3 (https://github.com/OlivierRaven/Koura_Mesocosm) and a rendered version of the analysis
4 is hosted at https://oliverraven.github.io/Koura_Mesocosm/. The primary raw dataset is
5 archived on Zenodo (<https://doi.org/...>). Peer review documents, including the cover letter
6 and reviewer responses, are available in the manuscript repository in the interest of open and
7 transparent science.
